

## **Supplementary Text and Results**

### **Appendix S1. Supplementary Methods**

**Stage 1 Country-specific Influenza-associated Mortality Estimates.** We first obtained estimates from 30 main countries using published data from the recent study by Iuliano et al [1] and data from three additional countries (Brazil, Sweden and Poland). All countries in the main analysis provided national vital statistics on respiratory mortality and most provided viral surveillance data (Main text Table 1). Because estimates from India and Kenya were based on verbal autopsy assessment of respiratory cause of death for a small or regional population sub-sample (1% of the total population in India and the Western Region of Kenya) [2], we elected to exclude both from the main analysis but used them in a sensitivity analysis to gauge the robustness of the global estimate. The main analysis is therefore based on 31 countries (Main text Table 1).

The modelling methods used to calculate influenza-associated mortality varied, with 26 of the 33 countries performing regression models with viral activity and seasonal terms as covariates, while the remaining 7 countries used Serfling models with seasonal terms only (reference [1] and Main text Table 1). Of the 7 countries using Serfling, 5 were in South America. Different seasonal terms were included in the models: most models included harmonic terms although a few used flexible spline functions; some also added temperature and humidity covariates ([1], Supplementary appendix, Appendix Table 2).

For Brazil, Poland and Sweden, we used negative binomial regression models driven by weekly viral activity, using cubic splines (5 or 6 degrees of freedom, depending on the country) to model seasonal baselines. The degree of freedom for the spline function was chosen based on minimization of auto-correlation. Viral activity indicators were based on the weekly percent positive for total influenza positive specimens reported to WHO FluNet and smoothed by a 3-wk average centered in the current week. Separate influenza coefficients were fit for separate influenza seasons.

**Stage 2: Multiple Imputation.** The method to extrapolate the global burden of influenza is based on a subset of world countries that have influenza-associated mortality estimates (Stage 1 sample) and has been described in detail elsewhere [5]. It involves two steps, a data creation step followed by a hierarchical regression modelling step to project the Stage 1 influenza burden estimates to 193 world countries. In the data creation step, we used statistical correlations between a set of country indicators (Table S1) and the Stage 1 mortality estimates to create a distribution of possible mortality

values for each of the countries without data. In the regression step, we applied a hierarchical linear random effects regression model to these distributions per country, to obtain a point estimate (with standard error) for the influenza burden estimates by country, region and the world. We provide more details on this approach in the next section.

We applied the Stage 2 methodology to data for each year separately, which ran from July 1 to June 30 for the Northern hemisphere and the actual calendar year for countries in the Southern Hemisphere or countries with tropical climates (Main text Table 1). We only included years for which we had 19 or more Stage 1 country estimates: specifically, the years 2002-2008 and 2010-2011, with 2009 pandemic year excluded (Table S2). To prepare the Stage 1 data for Stage 2 modelling, we replaced negative excess mortality estimates with zero and excluded country estimates for which the point estimate and confidence intervals were all zero (this only happened for the Netherlands).

**Stage 2 Point Estimate Generation Procedure.** To estimate global, regional and country-specific excess mortality rates using the created datasets (20 imputed data-points per country per year), we applied a hierarchical linear random effects regression model. For each year, we calculated the mortality rates simultaneously (in one model) for each country, region, and the world. Separate models were fitted for each year.

The model used was:

$$Y_{ij} = \beta_0 + \sum_{r=1}^R \beta_r X_r + \sum_{f=1}^{n-1} \beta_f X_f + \mu_j + \sum_{f=1}^n \varepsilon_f$$

Where:

Y = imputed individual measurement rates per country

i = individual measurement (1 to 20 for imputation)

j = country (1 .... 193)

$\mu_j$  = between country variance;  $\mu_j \sim N(0, \tau_j^2)$

$\varepsilon_f$  = error variance for every imputed dataset, normally distributed;  $\varepsilon_f \sim N(0, \tau_f^2)$

$X_r$  = dummy variable for the six WHO regions ( $r=1\dots6$ ), rescaled indicators ((0,1)-1/6)

and is 0 if  $r=7$

$r=7$ , countries not belonging to a region (1 if  $r=7$  else 0)

$r$  = WHO region (1..7)

$X_f$  = dataset indicator, rescaled indicator coding ((0,1)-1/n)

$f$  = imputed datasets (1..20)

n=number of datasets (20)

To estimate the different rates as predictions based on the model:

$$\text{World} = \beta_0$$

$$\text{WHO Region} = \beta_0 + \sum \beta_r$$

$$\text{Country} = \beta_0 + \sum \beta_r + \mu_j$$

We performed the imputation procedures with the Amelia software package [3], and used the MLwiN v2.3 package for the analysis model [4].

**Stage 2 model outputs.** Table S3 presents the results from the hierarchical linear random effects regression model for over 65 age and under 65 years models by year (2002-2008 and 2010-2011).

## **Appendix S2. Supplementary Results**

### **Stage 1 sensitivity analyses**

We compared the Stage 1 estimates from our 31 initial countries to their corresponding Stage 2 projected value and found excellent agreement (pairwise correlation >0.95, median difference 17% in under 65 years and 15% in 65 years & above, Figure S1).

### **Additional GLM findings**

**Time trends.** We found significant declining time trends in influenza-associated Stage 2 mortality estimates in both age groups between 2002 and 2011, equivalent to a 3.5% (95% CI 2.8 - 4.2%) annual decline in the >65 year old age group and a 4.8% (4.1 – 5.4%) decline in the <65 year age group (Table S3). However, we saw no evidence of time trends in the smaller sample of 31 Stage 1 countries.

Interpreting the time trends is difficult. Because of the short time period and the pandemic interruption in 2009, the trends finding could merely be an artefact short-term perturbations in influenza circulation in the peri-pandemic period; indeed, the beginning of our study period coincided with severe epidemics caused by antigenically novel A/H3N2 viruses. Alternatively, these declining trends could reflect long-term improvements in healthcare not specific to influenza, or perhaps increasing influenza vaccination or drug treatment. The effect of influenza vaccination certainly deserves further study as more data years become available.

**Other factors.** Additional analyses to identify predictors of excess mortality in Stage 1 data as in were consistent with our main analysis using Stage 2 estimates, and pointed at subtype and regional effects, as well as health and socio-economic indicators (Table S3). These results confirm the importance of country-specific development indicators in driving influenza-related mortality, although the power of this analysis is limited by the lack of less developed countries in the Stage 1 sample.

## SUPPLEMENTARY TABLES

**Table S1.** Country indicators used as factors in the Stage 2 model [5] that projects the measured Stage 1 seasonal influenza mortality.

Indicator Number	Indicator
1	WHO region (Africa, Americas, Eastern Mediterranean, Europe, South-East Asia, Western Pacific)
2	Age group (all cause mortality rates 10-14-15-64, 65+)
3	Physician density (per 10,000 population)
4	Obesity (percent with body mass index $\geq 30\text{kg}/\text{m}^2$ )
5	Population density (per $\text{km}^2$ )
6	Major infectious diseases (percent HIV positive and tuberculosis prevalence)
7	Gross National Income (GNI) per capita (US dollars)
8	Rural population (percent)
9	Population age structure: percent $\leq 15$ and $\geq 60$ years
10	Latitude (absolute value)

\* Note (applying to all model outputs in Table 3): The 20 Factors represent the 20 imputed datasets (as the Stage 2 procedure produces 20 imputed data points per country per year, and each dataset has a different average) which are included in the hierarchical linear random effects regression model to calculate the point estimates (with standard error) by country, region and the world, see the formula of the data analysis step below, where f stands for imputed dataset. “Factor n” in the table above represents the term  $\beta_f X$  and “Factor n error” represents  $\varepsilon_f$ .

The Stage 2 model contains many components, many of which are nuisance parameters used to control for bias and to adjust for the way the datasets are created. Useful fixed effects components are the ‘Intercept world,’ which yields the global rate, and the ‘Regional’ parameters (e.g. Africa and Eastern Mediterranean), which yield the regional rates, and the ‘Between countries’ variance, which yields the random effects component. Note that overall fit statistics (e.g.  $R^2$ ) have little meaning here due to the large number of nuisance parameters; we used the reliability coefficient instead.

**Table S4: Predictors of influenza-related excess mortality rates by age group and country.**

Same as in Main text Table 3 but for the subset of countries that have Stage 1 estimates. Results of a multivariate mixed generalized linear regression model applied to 28 countries for which vital statistics were modeled to assess influenza burden over 9 years, 2002-2011, after exclusion of the pandemic period. Best model selected by Akaike's information criterion (AIC). This analysis does not take into account the errors in Stage 1 estimates

Western Pacific	-4.22 (0.88) †††	17.88 (33.14)

\* Significance level: †,  $<0.05$ ; ††,  $<0.001$ ; †††,  $<0.0001$ . We used the Kenward-Roger approximation to obtain approximate degrees of freedom for the mixed model, and the  $t$ -distribution for  $p$ -values.

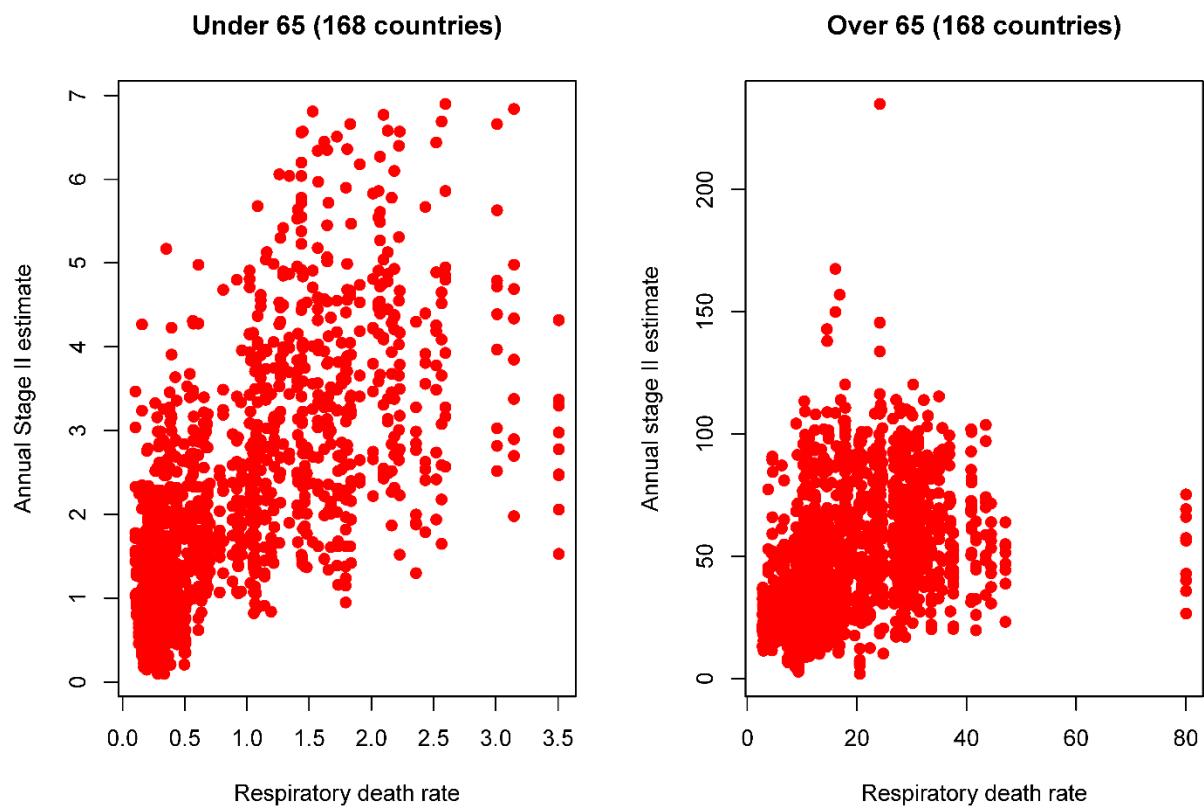

† Healthcare And Quality Index (HAQI), reflecting amenable mortality causes (32 causes were considered). Higher values indicate higher healthcare access and quality.
